(Dated: February 6, 2008)

We present a detailed theoretical study on the thermodynamic properties of impure quasi-one dimensional unconventional charge-, and spin-density waves in the framework of mean-field theory. The impurities are of the ordinary non-magnetic type. Making use of the full self-energy that takes into account all ladder-, and rainbow-type diagrams, we are able to calculate the relevant low temperature quantities for arbitrary scattering rates. These are the density of states, specific heat and the shift in the chemical potential. Our results therefore cover the whole parameter space: they include both the self-consistent Born and the resonant unitary limits, and most importantly give exact results in between.

I. INTRODUCTION

In the past few decades many papers have been published dealing with the mean-field theoretical study of impurity scattering in either density waves (DW) or superconductors (SC). It has been pointed out earlier by several authors,[1,2,3] that non-magnetic impurities should have a pair-breaking effect on conventional density waves, similar to the one caused by paramagnetic impurities in SCs, found first by Abrikosov and Gor'kov (AG).[4] In this connection, the original AG theory,[5,6] developed specifically for the treatment of dilute, randomly distributed magnetic impurities in s-wave BCS superconductors, was later successfully applied with minor modifications for example in excitonic insulators,[7,8] and in the context of conventional charge and spin density waves with constant gap.[9,10] All these studies however, particularly because of the assumed dilute concentration, considered the impurity effects on the level of second order self-consistent Born approximation, and retained only the first nontrivial self energy insertion in the proper self energy caused by impurities. On the other hand, in case of strong scatterers, higher-order diagrams in the self energy might be of importance, especially at low temperatures in view of the anomalous behavior of the normal state (Kondo effect).[11,12]

After the discovery of unconventional superconductors, the extension of the field of density waves to DWs with wave-vector dependent gap $\Delta(\mathbf{k})$ (termed unconventional) arose in a natural way. Unconventional density waves (UDW), either spin or charge, have the interesting property, that though a robust thermodynamic phase transition is clearly seen in experiments, they lack any spatial modulation of charge or spin density due to the zero average of the gap over the Fermi surface. Consequently, the phase transition cannot be caught in the act with conventional means like x-ray or NMR. This state of affairs is usually referred to as the "hidden order" in recent literature.[13] One of the main reasons of interest on UDWs arises from high-T_c superconductors, where one of the competing models in the pseudogap phase is the d-density wave state, a kind of two-dimensional unconventional charge density wave (UCDW).[14,15,16] The relevance of UDWs in general is further emphasized by recent studies such as: the mysterious low temperature micromagnetic phase of some heavy fermion compounds seem to be described rather well by unconventional spin density wave (USDW),[17,18] the pseudogap phase of $(\mathrm{TaSe}_4)_2\mathrm{I}$ is explained, at least on qualitative level, by a coexisting CDW+UCDW order,[19,20] and finally the ground state of the transition metal dichalcogenid 2H-TaSe_2 was attributed to an f-wave UCDW lately.[21] As to the quasi-one dimension, which is the natural place of occurence of DWs, one of the most likely candidate for possessing some kind of CDW of unconventional type in its low temperature phase is the organic conductor α-(BEDT-TTF)$_2$KHg(SCN)$_4$. In the past few years this salt has been investigated extensively,[22,23,24,25,26,27] and recently the experimental findings of these latter works have been explained rather well by a quasi-one dimensional UCDW, including the threshold electric field,[28,29,30] the angular dependent magnetoresistance,[31,32] and the magnetothermopower and Nernst effect[33].

Impurity scattering in UDWs and unconventional SCs has been investigated many times from different aspects, but the theoretical formulations were limited to include either the weak scattering Born or the resonant unitary limit.[34,35,36] The main outcome of these studies is that the presence of non-magnetic impurities leads to the destruction of ground state. The present work is partly motivated by the surprising discovery that the Ni impurities enhance the energy gap of d-wave DW in underdoped YBCO.[37] In light of this, our aim in this paper is to explore the intermediate regime as well by making use of the full self energy in the non-crossing approximation. We give a detailed analysis of the thermodynamic properties of UDWs, without making any constraint on the strength of the forward and backscattering parameters. As we shall see, our general formulas suggest that non-magnetic impurities always suppress density wave ground state. The enhancement of the pseudogap in YBCO by magnetic Ni impurities is proposed to originate from a different mechanism discussed in a separate publication.[38] Calculations similar to this has been carried out for heavy fermion superconductors[39] and d-density waves[40,41]. To the best of our knowledge however, this question in quasi-one dimensional UDWs has not been addressed so far.

The article is organized as follows: in Section 2 we present the formalism necessary to treat impurity scattering in the non-crossing approximation in unconventional density waves. In Section 3 we calculate the relevant thermodynamic quantities in the low temperature phase. Section 4 is dedicated to the analysis of the quasiparticle density of states, and finally Section 5 is devoted to our conclusions.

II. FORMALISM

We begin with the mean-field Hamiltonian describing pure quasi-one dimensional density waves[42,43]

$$H_0 = \sum_{\mathbf{k},\sigma} \xi(\mathbf{k})(a^+_{\mathbf{k},\sigma} a_{\mathbf{k},\sigma} - a^+_{\mathbf{k}-\mathbf{Q},\sigma} a_{\mathbf{k}-\mathbf{Q},\sigma}) + \Delta_\sigma(\mathbf{k}) a^+_{\mathbf{k},\sigma} a_{\mathbf{k}-\mathbf{Q},\sigma} + \Delta^*_\sigma(\mathbf{k}) a^+_{\mathbf{k}-\mathbf{Q},\sigma} a_{\mathbf{k},\sigma}, \tag{1}$$

where $a^+_{\mathbf{k},\sigma}$ and $a_{\mathbf{k},\sigma}$ are the creation and annihilation operators for an electron in a single band with momentum $\mathbf{k}$ and spin σ. The best nesting vector is given by $\mathbf{Q} = (2k_F, \pi/b, \pi/c)$, and the $\mathbf{k}$ sum in Eq. (1) is restricted to the reduced Brillouin zone as usual: k_x runs from 0 to $2k_F$, with k_F being the Fermi wave vector. Our system is based on an orthorhombic lattice with lattice constants a, b, c towards directions x, y, z. The system is highly anisotropic, the kinetic energy spectrum of the particles linearized around the Fermi surface reads as

$$\xi(\mathbf{k}) = v_F(k_x - k_F) - 2t_b \cos(bk_y) - 2t_c \cos(ck_z), \tag{2}$$

and the quasi-one dimensional direction is the x axis. For (U)CDWs the density wave order parameter $\Delta_\sigma(\mathbf{k})$ is even, while for (U)SDW systems it is an odd function of the spin index. In the case of conventional density waves the order parameter is constant on the Fermi surface.[42] As opposed to this, for unconventional condensates it depends on the perpendicular momentum and has different values at different points on the Fermi surface. The precise $\mathbf{k}$-dependence is determined by the matrix element of the electron-electron interaction through the gap equation.[43]

The interaction of the electrons with non-magnetic impurities is described by the Hamiltonian[34,35,44]

$$H_1 = \frac{1}{V} \sum_{\mathbf{k},\mathbf{q},\sigma,j} e^{-i\mathbf{q}\mathbf{R}_j} \Psi^+_\sigma(\mathbf{k}+\mathbf{q}) U(\mathbf{R}_j) \Psi_\sigma(\mathbf{k}), \tag{3}$$

$$U(\mathbf{R}_j) = \begin{pmatrix} U(0) & U(\mathbf{Q})e^{-i\mathbf{Q}\mathbf{R}_j} \\ U^*(\mathbf{Q})e^{i\mathbf{Q}\mathbf{R}_j} & U(0) \end{pmatrix}, \tag{4}$$

where V is the sample volume, $\mathbf{R}_j$ is the position of the jth impurity atom on the lattice, and the momentum space is divided into $\mathbf{k}$ and $\mathbf{k}-\mathbf{Q}$ subspaces (right- and left-going electrons) by introducing the spinor

$$\Psi_\sigma(\mathbf{k}) = \begin{pmatrix} a_{\mathbf{k},\sigma} \\ a_{\mathbf{k}-\mathbf{Q},\sigma} \end{pmatrix}. \tag{5}$$

We have neglected the small $\mathbf{q}$-dependence of the matrix elements (i.e. the Fourier components of the impurity potential) in Eq. (4). This is because we are dealing with quasi-one dimensional density wave systems whose Fermi surface consists of two almost parallel sheets at the points $\pm k_F$. Consequently, two relevant scattering amplitudes can be distinguished: the forward $U(0)$ and the backward scattering parameter $U(\mathbf{Q})$, respectively. We believe that we can capture the essence of physics with this approximation. This is indeed the case, at least as long as only thermodynamics is concerned. Investigating the effect of pinning, and the sliding density wave however, requires the inclusion of the small $\mathbf{q}$ contribution.[28,29]

Now, with all this, the electron thermal Green's function for the interacting system using Nambu's notation is defined as[6]

$$G_\sigma(\mathbf{k}, i\omega_n) = -\int_0^\beta d\tau \langle T_\tau \Psi_\sigma(\mathbf{k},\tau) \Psi^+_\sigma(\mathbf{k},0)\rangle_H e^{i\omega_n\tau}, \tag{6}$$

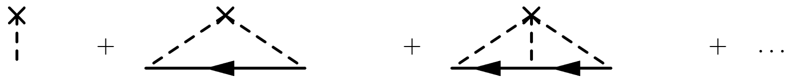

FIG. 1: Non-crossing self energy corrections due to impurity scattering. The solid line denotes the electron propagator G, while the dashed line is for the electron-impurity interaction. Dashed lines coming from the same cross represent successive scattering of the electron on the same impurity.

where the Green's function is chosen to be diagonal in spin indices, and the subscript H refers to the total Hamiltonian $H = H_0+H_1$ with which the expectation value should be taken. The propagator for the pure system without impurities is readily evaluated as

$$G^0_\sigma(\mathbf{k}, i\omega_n) = -\frac{i\omega_n + \xi(\mathbf{k})\rho_3 + \rho_1\mathrm{Re}\Delta_\sigma(\mathbf{k}) - \rho_2\mathrm{Im}\Delta_\sigma(\mathbf{k})}{\omega_n^2 + \xi(\mathbf{k})^2 + |\Delta_\sigma(\mathbf{k})|^2}, \tag{7}$$

where ρ_i $(i = 1, 2, 3)$ stand for the Pauli matrices acting on the space of left-, and right-going electrons.

From now on we will drop the spin indices since they are irrelevant for our discussion on thermodynamic properties, and our results apply to both unconventional spin-, and charge-density waves as well. Furthermore, we choose the momentum dependence of the order parameter appearing in the zeroth order Green's function as $\Delta(\mathbf{k}) = \Delta e^{i\phi}\sin(bk_y)$, where the phase ϕ is unrestricted due to incommensurability. Though the impurities we shall shortly introduce in the system are able to pin down the phase,[28,29] performing the usual impurity average restores translational invariance and consequently the phase degree of freedom. Thus, for brevity we fix the phase to be $\phi = 0$ and without the loss of generality consider a real order parameter. As to the specific $\mathbf{k}$-dependence, had we chosen a gap with cosine function or with the z component of the wave vector would not alter our results.

Let us now turn our attention to the self-energy $\Sigma(\mathbf{k}, i\omega_n)$ caused by the non-magnetic impurities. In diagrammatic language, the non-crossing approximation (NCA) retains only those diagrams where no two interaction lines cross each other. A simple subset of such diagrams are usually referred to as the ladder-type diagrams describing successive scattering processes on the same and single impurity atom. In case the particle lines appearing in these diagrams are not the bare G^0 but the dressed propagators G, then all the rainbow-type diagrams are included as well, and the NCA becomes full and self-consistent, see Fig. 1. The coupled equations valid for UDW are[34]

$$G^{-1}(\mathbf{k}, i\omega_n) = G_0^{-1}(\mathbf{k}, i\omega_n) - \Sigma, \tag{8}$$

$$\Sigma = n_i\frac{U(0) - g(U(0)^2 - |U(\mathbf{Q})|^2)}{1 - 2gU(0) + g^2(U(0)^2 - |U(\mathbf{Q})|^2)}, \tag{9}$$

where $g = (2V)^{-1}\sum_{\mathbf{k}}\mathrm{Tr}G(\mathbf{k}, i\omega_n)$ is the local Green's function, n_i is the impurity concentration, and according to the ignorance of small $\mathbf{q}$-dependence of scattering amplitudes (see Eq. (4) and subsequent argument), the self energy turns out to be momentum independent $\Sigma(\mathbf{k}, i\omega_n) \equiv \Sigma(i\omega_n)$. We shall note here that the impurity concentration should be small enough in order for the NCA to be applicable and reliable. Quantitatively it means that the self energy should be much smaller than the bandwith $W = 2v_F k_F$, otherwise the contribution of crossing diagrams cannot be neglected and retaining the non-crossing class of diagrams only becomes inadequate. Moreover, at large enough concentration the standard independent average over the impurity positions on the lattice breaks down (for the impurity average performed on Σ, see Ref. 34). We will see shortly however, that because of pair-breaking, we have a natural limit on n_i which is of the order of 1%. Staying in this region of concentrations should be within the bounds.

The ansatz-solution G of the closed pair of equations above reads as

$$G(\mathbf{k}, i\omega_n) = -\frac{i\tilde{\omega}_n + \xi(\mathbf{k})\rho_3 + \Delta(\mathbf{k})\rho_1}{\tilde{\omega}_n^2 + \xi(\mathbf{k})^2 + \Delta(\mathbf{k})^2}, \tag{10}$$

where, in contrast to conventional systems with constant gap, only the Matsubara frequency gets renormalized.[34,35] The order parameter remains unaffected due to the unconventional nature of the gap with vanishing Fermi surface average. This is also known for quasi-one dimensional superconductors.[45] With the aid of the explicit expression in Eq. (10), g is calculated easily, and the renormalization condition for the Matsubara frequency follows as

$$i\tilde{\omega}_n = i\omega_n + \delta\mu - \Sigma, \tag{11}$$

$$g = -N_0\frac{i\tilde{\omega}_n}{\sqrt{\tilde{\omega}_n^2 + \Delta^2}}K\left(\frac{\Delta}{\sqrt{\tilde{\omega}_n^2 + \Delta^2}}\right), \tag{12}$$

where $N_0 = 1/(\pi v_F bc)$ is the normal state density of states per spin, $K(z)$ is the complete elliptic integral of the first kind, and we have introduced a shift in the chemical potential $\delta\mu$ by hand in Eq. (11). This we need in order to keep the particle number conserved in the system, since the presence of impurities on a macroscopic scale causes the particles to either flow in or out of the system depending on the sign and magnitude of the forward and backward scattering parameters.

Impurity scattering from the theoretical point of view has been investigated extensively in the literature. These related works can be usually classified into one of two groups depending on the formalism used to capture the strength of the scattering process. However, both approaches are limiting cases of the formalism introduced here. In the second order Born approximation,[9,34,35,46] applicable for weak impurity scattering, the self energy simplifies to $\Sigma = n_i U(0) - n_i g(U(0)^2 + |U(\mathbf{Q})|^2)$, and $\delta\mu = n_i U(0)$. On the other hand, for strong scattering the unitary limit is widely used,[35,47,48,49] where $\Sigma = -n_i/g$ and $\delta\mu = 0$.

The aim of the present work is to make use of the full self energy defined in Eq. (9). Without making any constraints on the strengths of the scattering parameters $U(0)$ and $U(\mathbf{Q})$, we give a unified theory of the full non-crossing approximation. With this general approach we are able to cover the whole parameter space, to reobtain the well known formulas in the weak and strong scattering limits, and most importantly to provide exact results in the intermediate regime. As we have already mentioned, similar calculations based on a self-consistent T-matrix approximation have been performed for heavy fermion superconductors[39], and then later for d-density waves[41] as well. In UDWs however this question is still open.

III. THERMODYNAMICS OF IMPURE UDW

Using the off-diagonal component of the Green's function in Eq. (10), the gap equation, that determines the temperature dependence of the order parameter in the impure system, reads as

$$\Delta = \frac{PT}{N}\sum_{\mathbf{k},\omega_n} \frac{\Delta\sin(bk_y)^2}{\tilde{\omega}_n^2 + \xi(\mathbf{k})^2 + \Delta^2\sin(bk_y)^2}, \tag{13}$$

where N denotes the number of sites. The effective coupling P favoring the sine dependence of $\Delta(\mathbf{k})$, and a factor of $\sin(bk_y)$ in the numerator comes from the kernel of the electron-electron interaction.[43] Now we derive the equation that determines the transition temperature T_c. Following Ref. 9, we reformulate Eq. (13) as

$$\ln\left(\frac{T}{T_{c0}}\right) = T\sum_{\omega_n}\left\{\frac{4\sqrt{\tilde{\omega}_n^2}}{\Delta^2}\left(E\left(\frac{i\Delta}{\tilde{\omega}_n}\right) - K\left(\frac{i\Delta}{\tilde{\omega}_n}\right)\right) - \frac{\pi}{|\omega_n|}\right\}, \tag{14}$$

where $E(z)$ is the complete elliptic integral of the second kind, and T_{c0} is the transition temperature of the pure UDW.[43] We note that the basic Eqs. (9) and (11-12) determining the renormalized frequency as a function of the bare frequency provide unphysical solutions as well. The physically correct solution, that involves the right analytic properties of the Green's function, is chosen according to: $\mathrm{sign}(\mathrm{Re}\tilde{\omega}_n) = \mathrm{sign}(\omega_n)$. In the region near the transition temperature T_c, where Δ is small, we can expand the right hand side of Eq. (14), and we obtain the celebrated Abrikosov-Gor'kov (AG) formula

$$-\ln\left(\frac{T_c}{T_{c0}}\right) = \mathrm{Re}\psi\left(\frac{1}{2} + \frac{|\Sigma_0''|}{2\pi T_c} + i\frac{\Sigma_0' - \delta\mu}{2\pi T_c}\right) + \psi\left(\frac{1}{2}\right), \tag{15}$$

where $\psi(z)$ is the digamma function and

$$\begin{aligned}
\Sigma_0' &\equiv \mathrm{Re}\Sigma(\Delta = 0)\\
&= 4n_i U(0) D^{-1}(4 + N_0^2\pi^2(U(0)^2 - |U(\mathbf{Q})|^2)), && (16)\\
\Sigma_0'' &\equiv \mathrm{Im}\Sigma(\Delta = 0)\\
&= -2\pi\,\mathrm{sign}(\omega_n) n_i N_0 D^{-1}[4(U(0)^2 + |U(\mathbf{Q})|^2) + \pi^2 N_0^2(U(0)^2 - |U(\mathbf{Q})|^2)^2], && (17)\\
D &= (4 + N_0^2\pi^2(U(0) + |U(\mathbf{Q})|)^2)(4 + N_0^2\pi^2(U(0) - |U(\mathbf{Q})|)^2). && (18)
\end{aligned}$$

Up to this point the shift in chemical potential played the role of a constant parameter, the value of which is determined by particle conservation via the integrated density of states. However, the calculation and analysis of the one particle density of states is the subject of the next section, therefore we anticipate here the result

$$\delta\mu = \Sigma_0'. \tag{19}$$

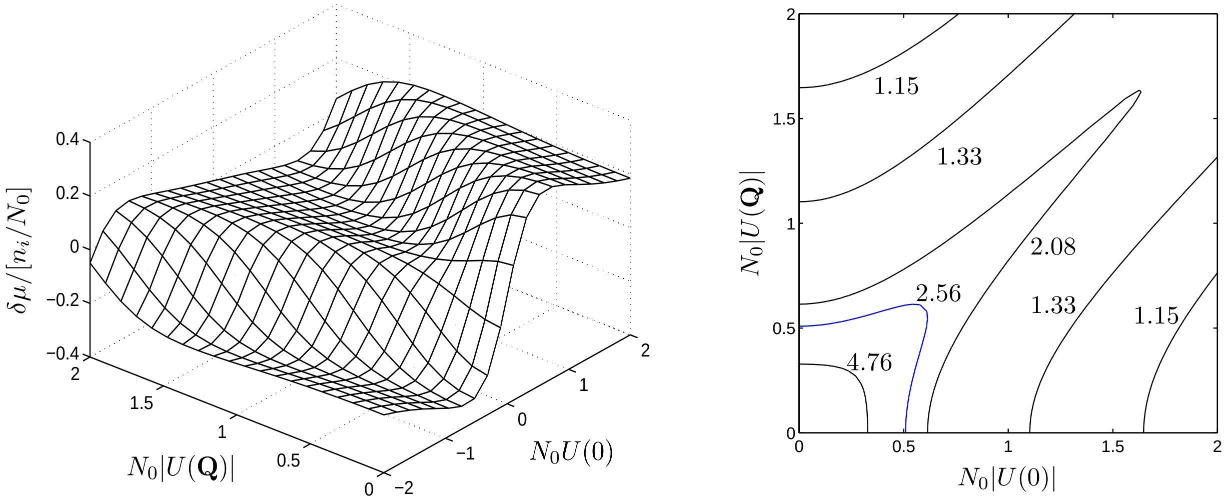

FIG. 2: (Color online) Left panel: the shift in the chemical potential due to impurity scattering as a function of the scattering amplitudes. Right panel: contourplot of the scattering rate $\Gamma/\Gamma_c = 1$ on the $U(0) - |U(\mathbf{Q})|$ plane for $n_i/n_c = 1.15$, 1.33, 2.08, 2.56 and 4.76. For example in the case of $n_i = 2.56n_c$, the variation of the scattering parameters is restricted to the region inside the contour (blue) with the corresponding label.

This result could have been presumed also from the AG formula in Eq. (15), because in the Born and resonant limits the argument of ψ is purely real.[34,35] In Fig. 2 (left panel) we plot $\delta\mu$ as a function of the scattering parameters. Note also, that the above formula is valid for normal metals with $\Delta = 0$ as well. With all this, we arrive to the final form

$$-\ln\left(\frac{T_c}{T_{c0}}\right) = \psi\left(\frac{1}{2} + \frac{\Gamma}{2\pi T_c}\right) + \psi\left(\frac{1}{2}\right), \tag{20}$$

where we have introduced the scattering rate $\Gamma = |\Sigma_0''|$. We see now, and shall point it out, that the AG formula is valid in general for arbitrary strength of the impurity scattering, and its applicability is not limited for the case of weak and strong scatterers only. The general form for Γ simplifies to the correct expression $(\Gamma_1 + \Gamma_2)/2$ in the Born limit, where $\Gamma_1 = \pi n_i N_0 U(0)^2$ and $\Gamma_2 = \pi n_i N_0 |U(\mathbf{Q})|^2$ are the forward and backward scattering rates, respectively.[34] On the other hand, it gives back the result $2n_i/(\pi N_0)$ known for strong scatterers.[35] Its critical value, where T_c vanishes, is given by $\Gamma_c = \pi T_{c0}/(2\gamma) = \sqrt{e}\Delta_{00}/4$, with $\gamma = 1.781$ being the Euler constant and Δ_{00} stands for the pure zero temperature order parameter. One can easily see that Γ is bounded as a function of the forward and backward scattering parameters, but scales with n_i. Consequently, this enables us to define a critical impurity concentration $n_c = \pi^2 N_0 T_{c0}/(4\gamma)$, below which $(n_i < n_c)$ the values of $U(0)$ and $|U(\mathbf{Q})|$ can be arbitrary, thereby including the Born and unitary limits as well, but above which $(n_i > n_c)$ the amplitudes are constrained into a finite region on the $U(0) - |U(\mathbf{Q})|$ plane around the origin. This is because otherwise the strength of the impurity scattering completely destroys the density wave condensate even at zero temperature. In the latter case apparently, only the Born limit is accessible. In Fig. 2 (right-panel) we show these regions and the corresponding confining contours of Γ/Γ_c. Using the parameters of α-(BEDT-TTF)$_2$KHg(SCN)$_4$, namely $T_c = 10$K, $v_F = 6 \times 10^4$m/s,[32] and lattice constant in the chain direction $a = 10^{-9}$m,[50] the critical concentration is estimated as $n_c = 0.01$. Close to Γ_c the transition temperature vanishes like[45]

$$\frac{T_c}{T_{c0}} = \frac{\sqrt{6}}{2\gamma}\ln^{\frac{1}{2}}\left(\frac{\Gamma_c}{\Gamma}\right). \tag{21}$$

Next, we proceed with the analysis of the zero temperature gap maximum. For brevity, in this paragraph $\Delta \equiv \Delta(T = 0)$. Similar calculations that lead to Eq. (14),[7,9] give in our case

$$\frac{\pi}{2}\ln\left(\frac{\Delta}{\Delta_{00}}\right) = \int_{-\infty}^{\infty}\frac{d\omega}{\Delta}\left(F\left(\frac{\tilde{\omega}}{\Delta}\right) - F\left(\frac{\omega}{\Delta}\right)\right), \tag{22}$$

where ω and $\tilde{\omega}$ are, respectively, the bare and the renormalized Matsubara frequencies (we omitted the subscript n), and

$$F(z) = \sqrt{1+z^2}E\left(\frac{1}{\sqrt{1+z^2}}\right) - \frac{z^2}{\sqrt{1+z^2}}K\left(\frac{1}{\sqrt{1+z^2}}\right). \tag{23}$$

The expression on the right hand side of Eq. (22), though is not adapted well for the numerical solution, is however convenient for further analytical calculations. Namely, it enables us to determine the behavior of the order parameter close to the critical scattering rate Γ_c. As the transition temperature and the gap maximum are closely related quantities, we expect similar tendency found for T_c in Eq. (21). Indeed, we obtain

$$\Delta = \frac{4\Gamma_c}{\sqrt{3}} \left(1 - \frac{2\pi}{9} \frac{\mathrm{Re}\Lambda}{\Gamma_c} \right)^{-1/2} \ln^{\frac{1}{2}} \left(\frac{\Gamma_c}{\Gamma} \right), \tag{24}$$

where $\Lambda = N_0 \partial \Sigma(g_0)/\partial g$, and $g_0 = g(\Delta = 0, \omega_n > 0)$. As we have just pointed out, for numerical purposes Eq. (22) shall be reformulated, and the following form is obtained

$$\frac{\pi}{2} \ln \left(\frac{\Delta}{\Delta_{00}} \right) = -2 \int_0^{C_0'} dz\, F(z) + \frac{2}{\Delta} \int_{C_0'}^{\infty} dz\, F(z) \mathrm{Im} \left(\frac{\partial \Sigma}{\partial z} \right) + 2C_0'' \int_0^1 d\lambda\, \mathrm{Im} \left\{ F(z) \left(1 - \frac{i}{\Delta} \frac{\partial \Sigma}{\partial z} \right) \right\}, \tag{25}$$

where $z = \tilde{\omega}/\Delta$, $C_0 = C_0' + iC_0''$ is the decomposition of C_0 into real and imaginary parts, and in the last integral $z = C_0' + i\lambda C_0''$. The C_0 parameter is the value of $\tilde{\omega}_n/\Delta$ at zero frequency as usual.[34,35,47] Note, that due to the true complex nature of the self energy Σ with finite real part, this generalized C_0 acquires a finite imaginary part leading to the appearance of the third term on the right hand side of Eq. (25). We present the result of the numerical solution of Eq. (25) in Fig. 3 (left panel) for fixed impurity concentration $n_i/n_c = 2.56$, that exceeds the critical threshold n_c. We shall emphasize, that the impurity concentration and the scattering parameters enter in the expression for Δ not through Γ, as is the case for (U)DWs[9,34,35] and superconductors[48] in the Born and unitary limits and also for T_c in the AG formula (see Eq. (20)), but enter through Σ and $\delta\mu$. In this respect, the plot shows the dependence of the zero temperature order parameter on the scattering amplitudes above the $U(0) - |U(\mathbf{Q})|$ plane, with n_i fixed. One can easily see, that the contour where Δ vanishes and Γ takes on the critical value Γ_c (see Eq. (24)), is just the one appearing in the right panel of Fig. 2, with the corresponding label 2.56.

The dependence of T_c on the scattering amplitudes is qualitatively the same as that of $\Delta(0)$ in Fig. 3, therefore is not presented here. However, the $\Delta(0)/T_c$ ratio might be of interest, and is shown in the right panel of Fig. 3. It is clear from the figure, that the ratio increases with increasing strength of impurity scattering. The lower bound is obviously the pure value $2\pi/(\gamma\sqrt{e}) = 2.14$.[43] Moreover, the maximum is reached on the confining contour

$$\max \left. \frac{\Delta(0)}{T_c} \right|_{\Gamma_c} = \sqrt{\frac{8}{5}}\pi \left(1 + \frac{8}{5} \frac{n_c}{n_i} \right)^{-1/2}. \tag{26}$$

Here we have used Eqs. (21) and (24). Now it is clear that as n_i increases, the overall maximum of the gap to T_c ratio is $\sqrt{8/5}\pi = 3.97$. This result has been obtained previously for quasi-one dimensional anisotropic superconductors based on a second order Born calculation.[45]

Close to T_c, $\Delta(T)$ vanishes in a square-root manner as does usually in mean-field treatments. In the series expansion of Eq. (14) for small Δ, the term of order Δ^2 provides

$$\Delta^2 = 8(2\pi T_c)^2 \frac{\rho\psi'(\frac{1}{2} + \rho) - 1}{\frac{3}{2}\psi''(\frac{1}{2} + \rho) + \frac{1}{12} \frac{\mathrm{Re}\Lambda}{T_c} \psi'''(\frac{1}{2} + \rho)} \left(1 - \frac{T}{T_c} \right), \tag{27}$$

where $\psi^{(n)}(z)$ is the nth polygamma function and $\rho = \Gamma/(2\pi T_c)$. The term $(12T_c)^{-1}\mathrm{Re}\Lambda$ in the denominator simplifies to $\rho/3$ in the Born,[34] and to $-\rho/3$ in the resonant unitary[48] limits.

Now we derive an expression for the order parameter close to absolute zero. The alternative formulas for the gap equation in Eq. (13) presented so far are not really convenient for our present purposes, thus with the usual contour integration technique we rewrite it as

$$\begin{aligned} \frac{\pi}{4} \ln \left(\frac{\Delta}{\Delta_{00}} \right) = & \int_{-\infty}^{0} \frac{d\omega}{\Delta} \left\{ \frac{\omega}{\Delta} \mathrm{Re} \left[K\left(\frac{\Delta}{\omega} \right) - E\left(\frac{\Delta}{\omega} \right) \right] - \mathrm{Re} \left[\frac{u}{\Delta} \left(K\left(\frac{\Delta}{u} \right) - E\left(\frac{\Delta}{u} \right) \right) \right] \right\} \\ & - \int_0^{\infty} \frac{d\omega}{\Delta} f(\omega) \left\{ \mathrm{Re} \left[\frac{u}{\Delta} \left(K\left(\frac{\Delta}{u} \right) - E\left(\frac{\Delta}{u} \right) \right) \right]_{\omega} - \mathrm{Re} \left[\frac{u}{\Delta} \left(K\left(\frac{\Delta}{u} \right) - E\left(\frac{\Delta}{u} \right) \right) \right]_{-\omega} \right\}, \end{aligned} \tag{28}$$

where Δ means $\Delta(T)$, and u is the analytically continued value of $i\tilde{\omega}_n$, namely $u = i\tilde{\omega}_n(i\omega_n \to \omega + i0)$. In addition $f(\omega)$ is the Fermi function and the subscripts $\pm\omega$ mean that u has to be evaluated at the corresponding frequency. This form will also be used for the evaluation of the low temperature specific heat shortly. We note that in the pure case, Eq. (28) simplifies considerably, and one can recognize the result found for pure d-wave superconductors.[51] This

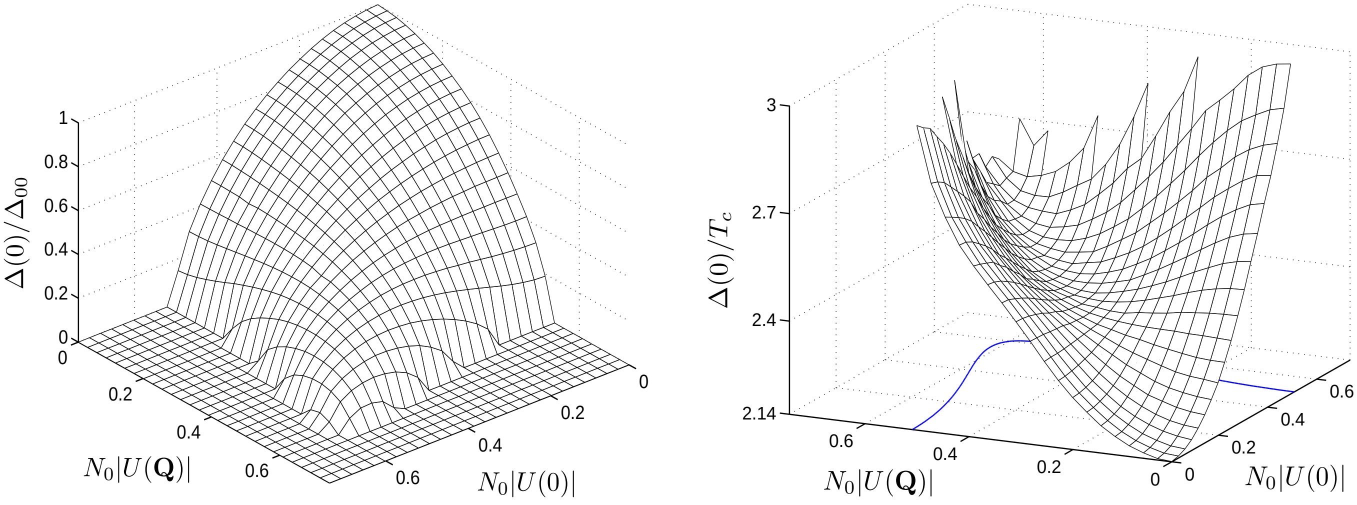

FIG. 3: (Color online) Left panel: the zero temperature order parameter $\Delta(0)$ as a function of the scattering amplitudes for fixed impurity concentration $n_i/n_c = 2.56$. Right panel: the $\Delta(0)/T_c$ ratio versus the scattering amplitudes for the same concentration as in the left panel. It is clear that the presence of impurities enhances this ratio from the pure result 2.14. For both panels, the contour of the domain on the $U(0) - |U(\mathbf{Q})|$ plane is the blue curve in Fig. 2 right panel.

is not surprising at all, as the similarity between the thermodynamics of UDW and d-SC are well-known.[34,35,43,47] From Eq. (28) we finally obtain

$$\Delta(T) = \Delta(0) - \frac{2\pi}{3}\frac{a}{1-b}\frac{T^2}{\Delta(0)}, \tag{29}$$

where the dimensionless parameters a and b are

$$a = -\Delta(0)\,\mathrm{Re}\left\{\left(1+\frac{\partial\Sigma(u_0)}{\partial u}\right)^{-1}\frac{\partial}{\partial u}E'\left(\frac{\Delta(0)}{u_0}\right)\right\}, \tag{30}$$

$$b = \frac{4}{\pi}\int_{-\infty}^{0}\frac{d\omega}{\Delta(0)}\mathrm{Re}\left\{(\Sigma-\delta\mu)\left(1+\frac{\partial\Sigma}{\partial u}\right)^{-1}\frac{\partial}{\partial u}E'\left(\frac{\Delta(0)}{u}\right)\right\}. \tag{31}$$

In Eqs. (30-31) $u_0 = i\Delta(0)C_0$, and the prime means differentiation with respect to the argument. With cumbersome calculations one can show that Eq. (29) gives back the known expression in the weak scattering Born limit.[34] The most important message of the above formula is obviously the fact that the presence of impurities changes the pure T^3 power law behavior[43] and transforms it to a faster T^2 decrease.

We shall close this section with the presentation of some relevant thermodynamic quantities, such as the grand canonical potential Ω, the entropy S and the specific heat C_V. Our starting point is the well-known formula for Ω due to Pauli, that is

$$\Omega - \Omega_0 = \int_0^1 \frac{d\lambda}{\lambda}\langle\lambda H_{int}\rangle, \tag{32}$$

where H_{int} is the interaction causing the phase transition. This formula gives us the thermodynamic potential difference $\delta\Omega$ between the normal and the DW phase. After lengthy calculations we obtain

$$\frac{\delta\Omega(T)}{N_0 V} = -\frac{\Delta^2}{4} + \frac{\Delta^2}{2}\ln\left(\frac{\Delta}{\Delta_{00}}\right) + 2\int_{-\infty}^{0} d\omega\,\omega\left(\frac{N(\omega)}{N_0} - \frac{N_p(\omega)}{N_0}\right) - 4T\int_0^{\infty} d\omega \ln(1+e^{-\beta\omega})\left(\frac{N^S(\omega)}{N_0} - 1\right), \tag{33}$$

where Δ means $\Delta(T)$ everywhere. Moreover $N(\omega)$ and $N_p(\omega)$ are, respectively, the quasiparticle density of states (DOS) in the impure and pure[43] systems, and finally $N^S(\omega)$ is the symmetrized DOS: $N^S(\omega) = (N(\omega) + N(-\omega))/2$. We will come back to the analysis of DOS in the next section, and we will see that it is not an even function indeed. We shall emphasize that the order parameter which is hidden in $N_p(\omega)$ and determines the energy scale, is that of

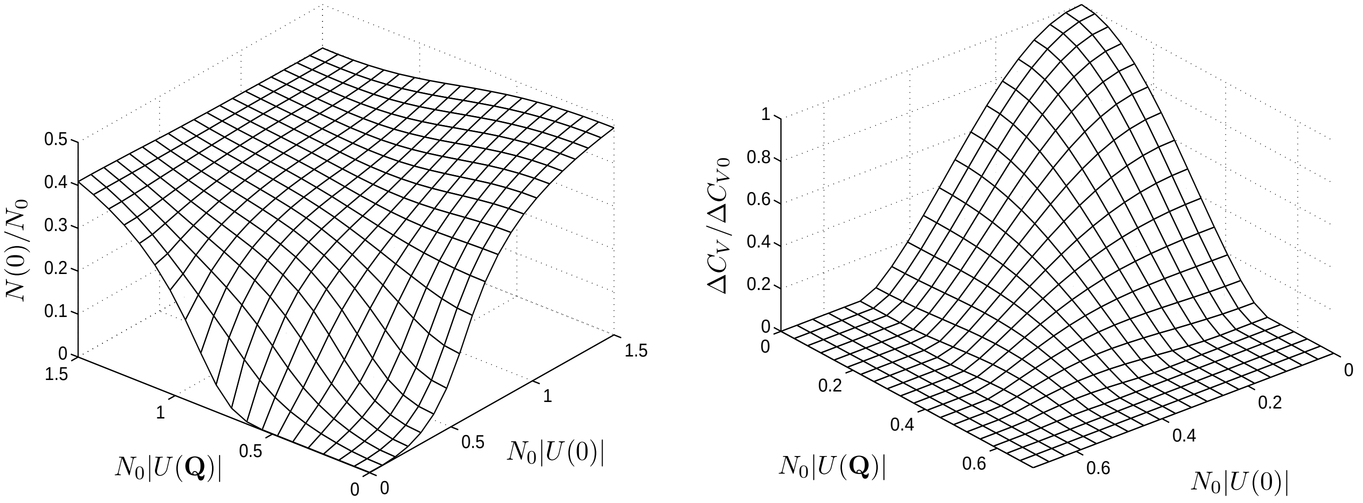

FIG. 4: Left panel: the residual density of states at the Fermi level for fixed impurity concentration $n_i/[N_0\Delta] = 0.3$. Right panel: the relative jump in the specific heat at the transition temperature T_c normalized to the pure value as a function of the scattering amplitudes for fixed impurity concentration $n_i/n_c = 2.56$.

the impure system. We also note that Eq. (33) is valid for all temperatures. In obtaining the above formula, we repeatedly made use of Eq. (28), and the following important relation

$$\frac{\partial}{\partial\omega}\mathrm{Re}\left\{E'\left(\frac{\Delta}{u}\right)\right\} = \frac{\pi}{2}\frac{\partial}{\partial\Delta}\frac{N(\omega)}{N_0}. \tag{34}$$

Now, one can easily check, that the temperature dependence through Δ does not contribute to the entropy since the gap equation ensures $\partial\delta\Omega/\partial\Delta = 0$. Consequently, in an UDW we simply get

$$S = 4\int_0^\infty d\omega N^S(\omega)\left(\ln(1+e^{-\beta\omega}) + \beta\omega f(\omega)\right), \tag{35}$$

which is the standard expression of a normal metal, except the DOS is that of the impure unconventional density wave. Note that due to the asymmetric feature of the DOS with respect to the Fermi energy, here $N^S(\omega)$ shows up. In those systems however, where the particle-hole symmetry is not violated, this feature remains hidden obviously.[49] From this, the low temperature specific heat is $C_V = (2\pi^2/3)N(0)T$. Here $N(0)$ stands for the residual density of states on the Fermi level and it is shown in the left panel of Fig. 4.

Around T_c the jump in the specific heat, normalized to the pure result, follows as

$$\frac{\Delta C_V}{\Delta C_{V0}} = -21\zeta(3)\frac{T_c}{T_{c0}}\frac{\left(1-\rho\psi'(\frac{1}{2}+\rho)\right)^2}{\frac{3}{2}\psi''(\frac{1}{2}+\rho)+\frac{1}{12}\frac{\mathrm{Re}\Lambda}{T_c}\psi'''(\frac{1}{2}+\rho)}, \tag{36}$$

where $\Delta C_{V0} = 16\pi^2 N_0 T_{c0}/(21\zeta(3))$, and it is shown in the right panel of Fig. 4 for fixed impurity concentration $n_i = 2.56n_c$. This result, just like Eq. (27), also becomes simpler in the case of weak and strong scattering limits, $(12T_c)^{-1}\mathrm{Re}\Lambda \to \pm\rho/3$, and we reobtain the familiar results.[48] Note that in Ref. 48 a factor of T_c/T_{c0} is missing, but is corrected by the same authors in a separate paper.[52]

IV. DENSITY OF STATES IN UDW

With the knowledge of the Green's function (see Eq. (10)), the quasiparticle density of states can be calculated as

$$\begin{aligned} N(\omega) &\equiv -\frac{1}{\pi V}\sum_{\mathbf{k}}\mathrm{Im}\,\mathrm{Tr}\left(G^R(\mathbf{k},\omega)\right) \\ &= \frac{2}{\pi}N_0\,\mathrm{Im}\left(\frac{u}{\sqrt{\Delta^2-u^2}}K\left(\frac{\Delta}{\sqrt{\Delta^2-u^2}}\right)\right) = \frac{2}{\pi}N_0\,\mathrm{Re}K\left(\frac{\Delta}{u}\right), \end{aligned} \tag{37}$$

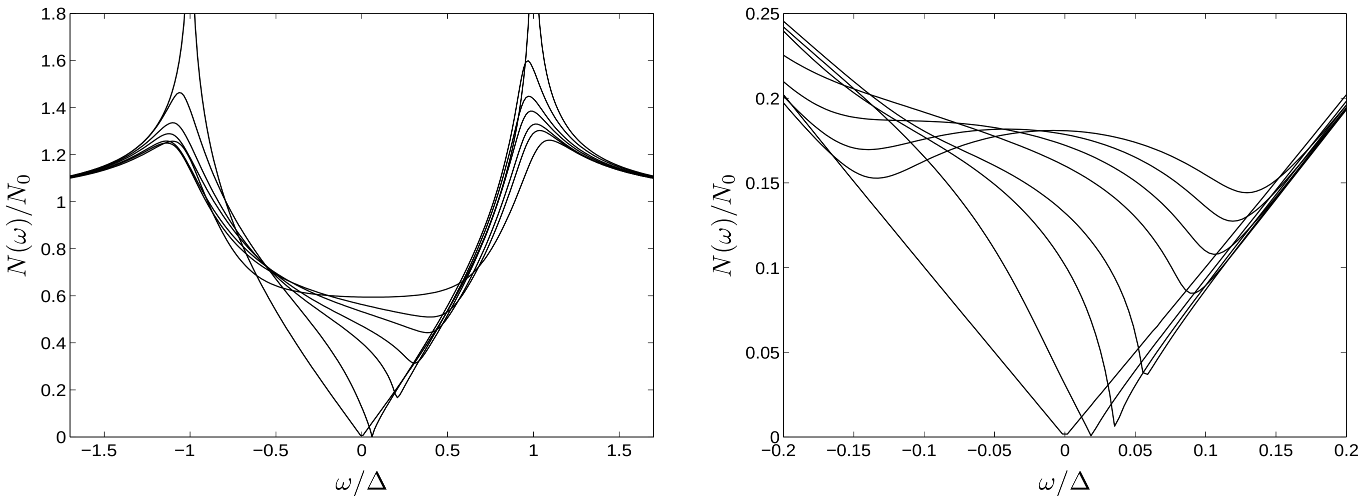

FIG. 5: Left panel: the quasiparticle density of states as a function of reduced energy for different values of the scattering amplitudes at fixed impurity concentration $n_i/[N_0\Delta] = 0.4$. $U(0)/|U(\mathbf{Q})| = 2$ and $N_0|U(\mathbf{Q})| = 0$, 0.2, 0.4, 0.6, 1, 1.5, and 20 for curves with increasing $N(0)$. Right panel: the density of states enlarged around the Fermi energy for $n_i/[N_0\Delta] = 0.02$, the ratio of the two scattering parameters is the same as in the left panel and $N_0|U(\mathbf{Q})| = 0$, 0.6, 1, 1.5, 3, 5, 10, and 50 for curves with increasing $N(0)$.

.

where $u = i\tilde{\omega}_n(i\omega_n \to \omega + i0)$ is the analytically continued value of the dressed Matsubara frequency. It is determined self-consistently from

$$u = \omega + \delta\mu - \Sigma(u), \tag{38}$$

and as we have already pointed out before, the physically correct solution is the one that ensures the right analytic properties of the retarded Green's function, that is $\mathrm{Im}u > 0$.

Now, we turn our attention to the shift in the chemical potential appearing first in Eq. (11), and here in the analytically continued version Eq. (38) as well. We have noted in the previous section also, that $\delta\mu$ was introduced by hand in order to maintain particle conservation. Its actual value is to be determined from the integrated DOS as

$$\int_{-\infty}^{0} d\omega(N(\omega) - N_0) = 0. \tag{39}$$

The second term in the integrand is the constant density of states of the pure metal, but it could equally be the DOS of the pure UDW. This is because the metal to UDW transition without impurities conserves the particle-hole symmetry and the even parity of the DOS, and as such, conserves particle number. The numerical solution of Eq. (39) confirms our expectation (based on the AG formula, see Eq. (15)), and we indeed find $\delta\mu = \Sigma_0'$.

With all this, we are now able to numerically evaluate the quasiparticle DOS defined in Eq. (37), and the results are shown in Fig. 5 for positive, i.e. repulsive forward scattering. Apparently, the main feature of these curves is the violation of particle-hole symmetry, similar to that found in d-density waves[40]. Namely, strictly speaking they are not even functions of energy. However, in the weak and strong scattering limits we reobtain even parity.[34,35,45] In addition, it is clear from the figures, that the logarithmic singularities at $\omega = \pm\Delta$ characteristic to UDWs in general are smoothed out due to the presence of scatterers. In the case of repulsive (attractive) scatterers the upper (lower) peak is larger. An other well-known effect of impurities is the finite residual DOS at the Fermi energy, $N(0) > 0$. For small forward and backward scatterings it disappears exponentially, it is shown separately in the left panel of Fig. 4. The right panel of Fig. 5 demonstrates the behavior of DOS on a smaller energy scale around the Fermi energy. For small n_i and large scattering amplitudes, we come up with the familiar result of the resonant limit,[35,47,53] that the density of states exhibits an island of localized states around the Fermi energy superimposed on the usual gapless density of states of the pure system, which is manifested in the nonmonotonic nature of the DOS close to $\omega = 0$.

After some algebra, the low-energy behavior turns out to be linear, and it reads

$$N(\omega) = N(0) + \frac{2}{\pi} N_0 \,\mathrm{Im}\left(\frac{K - E}{\sqrt{1 + C_0^2}}\left(1 + \frac{\partial\Sigma(u_0)}{\partial u}\right)^{-1}\right)\frac{\omega}{\Delta}, \tag{40}$$

where the argument of the elliptic integrals is $1/\sqrt{1+C_0^2}$. This is to be contrasted with the ω^2 contribution of the extreme limits. On the other hand, at high energies the density of states reaches the normal state value as

$$N(\omega) = N_0 \left(1 + \frac{\Delta^2}{4}\frac{\omega^2 - \Gamma^2}{(\omega^2+\Gamma^2)^2}\right). \tag{41}$$

This is what we find in the second order Born calculation,[34] except that now Γ is defined by the general formula $\Gamma = |\Sigma_0''|$ (see also Eqs. (17-18)). It is valid for arbitrary strength of impurity scattering parameters.

V. CONCLUSION

We have studied the effect of non-magnetic impurities in quasi-one dimensional unconventional charge and spin density waves within mean-field theory. The focus has been on the thermodynamic response of the system. As the impurities are of the ordinary non-magnetic type, the spin degrees of freedom in the condensate play no role, leading to the same conclusions for both types of UDW. As opposed to the usual treatment of impurity scattering in density waves and superconductors (i.e. the Born and unitary limits), we do not put any constraint on the strength of forward and backward scattering amplitudes, but make use of the full self energy obtained in the self-consistent non-crossing approximation (NCA). Namely, the applied proper self energy includes all ladder-, and rainbow-type diagrams to infinite order. In this regard, our NCA is full. We than repeatedly took advantage of the fact, that our generalized formulas contain the familiar results of the weak and strong scattering limits, and we reobtained them indeed. On the other hand, our results provide explicit expressions in the intermediate regime as well.

We started our investigation with the transition temperature and the order parameter affected by the scatterers. We have found that, with a suitable redefinition of the scattering rate compared to either the Born or the unitary expressions, the Abrikosov-Gor'kov formula holds in this general case as well. Its validity can be therefore extended to arbitrary scattering amplitudes. The analysis of the AG formula allows one to introduce a critical impurity concentration, below which ($n_i < n_c$) the impurity potential, whatever strong it is, cannot break down the density wave condensate. However, if n_i exceeds the critical threshold n_c, the order of which is estimated around 1%, the scattering amplitudes cannot be arbitrary large and only the Born limit is accessible. An interesting consequence of impurity presence is the appearance of a shift in the chemical potential $\delta\mu$, the inclusion of which is necessary in order to conserve particle number. We gave an explicit and exact expression for $\delta\mu$ as a function of the scattering amplitudes and concentration, that is valid in a normal metal as well. The overall maximum of the zero temperature gap to T_c ratio was found to be the same ($\sqrt{8/5}\pi = 3.97$) as in anisotropic quasi-one dimensional superconductors.

The most eye-catching feature of impurities is definitely the violation of particle-hole symmetry manifested in the asymmetric quasiparticle density of states. Strictly speaking, the DOS is not an even function of energy with respect to the proper Fermi energy, that is the pure Fermi energy shifted by $\delta\mu$. The asymmetry is most apparent around $\omega = 0$, where the low frequency behavior is linear as opposed to the quadratic form of the extreme limits. This also involves that the minimum of DOS is not at the Fermi energy. In addition, the peaks around $\omega = \pm\Delta$, the residues of logarithmic singularities of the pure DW, become asymmetric as well: in case of repulsive (attractive) scatterers the upper (lower) peak is larger. In unconventional DWs, at any finite scattering strength the valley of the DOS around the Fermi energy is filled in, leading to normal electronlike behavior very close to absolute zero, but the reduced density of states compared to the normal state signals the effect of the condensate. Taking the weak and strong scattering limits of the DOS, one regains particle-hole symmetry, and can easily reobtain the familiar lineshapes of the Born and unitary limits, in particular for instance the island of localized states around $\omega = 0$ in the latter case.
